Keywords: Clonidine; Maternal hypotension; Labour analgesia

Letter to Editor

Clonidine is an alpha-2-agonist that has been used in perioperative medicine for several purposes: premedication, neuraxial analgesia adjuvant to promote hemodynamic stability, anti-sialagogue and treatment of peri-operative shivering. The duration of action of this drug is approximately 12 hours. Recently, anesthesiologists are being interested in the use of clonidine for labor analgesia, both as intrathecal or epidural. Primigravida, 25 years old, 38 weeks of pregnancy, requested analgesia for vaginal delivery with 3cm cervical dilatation. After venous puncture, epidural interspace L4-L5 was punctured, with the loss of resistance technique. Then, 20ml of bupivacaine 0.065% with sufentanil (10µg) and clonidine (37.5µg) was administered. The catheter was introduced 5cm into the epidural space. After four hours, with cervical dilatation of 6cm, it was necessary to administer another dose and 12ml bupivacaine 0.065% was administered. After two hours it was necessary to give another shot of 12ml of 0.08% bupivacaine. After 8 hours of labor, one female healthy baby (Apgar 9/9) was born. The procedure was uneventful, and blood loss was usual. Half an hour later, the patient complained of feeling dizzy, presenting a heart rate of 52 bpm and blood pressure=83/35. Hypotension was treated immediately with epinephrine 20mg. She was transferred to the post-anesthetic room stable, where after an hour the patient presented hypotension again and 51 bpm, with profuse sweating and cold extremities. A dose of 35mg of ephedrine, volume expansion with 500ml of hydroxyethyl starch 6% and 1000ml of saline was infused with good clinical response. The use of clonidine for epidural labor analgesia has been extensively studied in the last decade, although not with doses below 60µg. The studies are controversial and performed with small patient sampling. Advantages of adding clonidine are reducing the mass of local anesthetics and opioids and their adverse effects. Disadvantages include a higher risk of maternal hypotension and bradycardia, sedation and neonatal behavioral change. Maternal hypotension is the most common adverse effect and may reduce uteroplacental blood flow. In a study by Van de Velde et al. (2009) clonidine 75µg associated with neostigmine 500mg prolonged analgesia and there was a decrease in the mass of epidural local anesthetic [1]. Epidural clonidine at a dose of 60µg added to bupivacaine, increased the duration of analgesia in 30%, with no major adverse effects when compared to bupivacaine without additives [2]. Studies with larger epidural clonidine (120-150µg) doses showed significant adverse effects such as sedation, hypotension, bradycardia and fetal heart rate abnormalities [3-6]. In one study, lower doses (30 µg) showed no significant benefits [7]. There is still no consensus about the use of epidural clonidine dosage. Suggested safe dosages range between 60µg and 75µg. Studies on epidural doses above 60µg were almost inexistent. Therefore, possibly, in specific cases, patients would benefit from receiving a mini dose of the drug like: difficulty to control the pain, intolerance to opioids or anxiety. This patient showed a significant hypotension, delayed and abruptly after 8 hours and 9 hours of its administration although there were no signals of relevant blood loss or peripartum cardiac disease.
