Abstract

A wide variety of secondary metabolites are synthesized from primary metabolites by plants which are used for the defense purpose. The secondary metabolites had a great scope in the pharmaceuticals, food additives, flavors, and industrial applications. The secondary metabolites are accumulated in the plant body due to stress. The production of plant secondary metabolites by cultivation of plants and chemical synthesis are important agronomic and industrial objectives. The chemical synthesis in most cases has not been economically feasible. The alternative promising option is in vitro culture, which represents a potential source of bioactive compounds, but very few cultures synthesize secondary metabolites in comparison to those produced in intact plants. Elicitor is the one of the stress agent that enhances the production of secondary metabolites in a particular tissue, organs and cells. Elicitors are classified into biotic and abiotic based on their nature. In recent years the use of elicitors in the plant tissue culture has opened a new path for the production of secondary metabolite compounds. Abiotic elicitors are of non-biological origin, includes metals, light, osmotic, drought, salinity, thermal and hormonal elicitors. Abiotic elicitors have different effects on the cellular processes in the plant system, such as growth, photosynthesis, carbon partitioning, carbohydrate and lipid metabolism, osmotic homeostasis, protein synthesis, and gene expression. The present review deals with the effects of different abiotic elicitors on the production of secondary metabolites from in vitro culture.

Keywords: Abiotic Elicitor; Callus; Cell Culture; Hairy Roots; Secondary Metabolites; Stress

Introduction

Plants are the complex organisms, it forms an important part of our everyday diet and their constituents and nutritional value have been intensively studied for decades. In addition to essential primary metabolites like carbohydrates, lipids and amino acids, higher plants are also able to synthesize a number of low molecular weight compounds called the secondary metabolites. Plant secondary metabolites are the diverse group of organic compounds that are produced by plants to facilitate interaction with the biotic and abiotic environment to establish the defense mechanism [1]. Plant secondary metabolites are unique sources of pharmaceuticals, food additives, flavors and industrially important biochemicals [2]. Plants will continuously produce the novel products as well as chemical models for new drugs in the coming centuries, because the chemistry of the majority of plant species is yet to be characterized. The advent of chemical analyses and the characterization of molecular structures have helped in precisely identifying these plants and correlating them with their activity under controlled experimentation. Despite advancements in synthetic chemistry, we still depend upon biological sources for a number of secondary metabolites including pharmaceuticals.

The plant, cell, tissue and organ culture techniques have emerged as an escapable tool with the possibilities of complimenting and supplementing the conventional method in plant breeding, plant improvement and biosynthetic pathways. Plant tissue culture plays a major role in conservation of germplasm, rapid clonal propagation, regeneration of genetically manipulated superior clones, production of secondary metabolites and ex vitro conservation of valuable phytodiversity [3,4]. Especially, plant cell and organ cultures are promising technologies to obtain plant-specific valuable metabolites [5]. Cell and organ cultures have a higher rate of metabolism than field grown plants because the initiation of cell and organ growth in culture leads to the rapid proliferation and to a condensed biosynthetic cycle [6]. Callus induction is necessary, as the first step, in many tissue culture experiments. Callus and cell suspension can be used for long-term cell cultures maintenance. Cell suspension culture systems could be used for large scale culturing of plant cells from which secondary metabolites could be extracted. The advantage of this method is that it can ultimately provide a continuous, reliable source of natural products. Due to the limited availability and complexity of chemical synthesis, plant cell culture becomes an alternative route for large-scale production of this desired compound [7].

Recent research in the in vitro culture systems, a wide variety of elicitors have been employed in order to modify cell metabolism. These modifications are designed to enhance the productivity of useful metabolites in the cultures of the plant cells/tissues. The cultivation period in particular, can be reduced by the application of elicitors, although maintaining high concentrations of product [6]. “Elicitor is a scientifically described term for stress factors that directly or indirectly triggers the inducible defense changes
in a plant system that results in an activation of array of protection mechanisms, including induction or expansion of biosynthesis of fine chemicals which do have a major role in the adaptation of plants to the stressful environment” [8].

**Classification of Elicitors**

Elicitors can be divided into two types on the basis of nature, biotic and abiotic. Biotic elicitors are the substances of biological origin, which includes polysaccharides originated from plant cell walls (chitin, pectin, cellulose, etc.) and micro-organisms. Abiotic elicitors consist of the substances that are of non-biological origin and are grouped into physical, chemical and hormonal factor. The classification of abiotic elicitor is depicted in figure 1.

**Abiotic Elicitors**

Abiotic elicitors have wide range of effects on the plants and in the production of secondary metabolites. The use of abiotic elicitors in plant cell cultures has received less attention compared with the biotic elicitors [9]. Recent research works explained the functions of many key genes, proteins, metabolites and molecular networks involved in plant responses to heavy metals, light, drought, salinity, thermal, hormonal and other abiotic elicitors [10]. In this review, actions of some of these elicitors are discussed in response to the production of secondary metabolites from in vitro culture.

**Effect on the Production of Secondary Metabolites**

**Chemical Elicitors:** Metals are influenced to alter the production of secondary metabolites by changing the aspects of secondary metabolism [11]. Metals have become one of the main abiotic stress agents for living organisms because of their increasing use in the developing fields like industry, agrotechnics, high bioaccumulation and toxicity [12]. Metals like Ni, Ag, Fe and Co have been shown to elicit the production of secondary metabolites in a number of plants [1]. In the cell suspension culture of *Vitis vinifera* the cobalt at all three used concentrations (5, 25 and 50 μM), Ag and Cd at low concentration (5 μM) were most effective to stimulate the phenolic acid production, and also increasing the 3-O-glucosyl-resveratrol up to 1.6-fold of the control level after the 4 hours (h) of treatments [12].

In hairy root cultures of *Ambrosia artemisiifolia*, an eightfold increase of thiarubrine A production was obtained when the 16-day-old culture was challenged with 50 mg/L vanadyl sulfate (VOSO₄) for 72 h [13]. In an attempt to enhance betalaines production, the hairy roots were exposed to metal ions [14]. It was reported that Ca²⁺, Ag⁺ and Cd²⁺ could improve the production of tropane alkaloids, scopalamine and hyoscyamine, in hairy roots cultures of *Brugmansia candida* [15,16]. Many kinds of heavy metal were also used as elicitors to induce accumulations of bioactive compounds in *Salvia miltiorrhiza*, such as Co²⁺, Ag⁺, Cd²⁺, Cu²⁺, Ce³⁺, La, Mn²⁺ and Zn²⁺ [17-20]. Among them, Ag⁺ was considered as an effective elicitor for phenolic compound and tanshinone production. Silver nitrate (AgNO₃) stimulated the production of tanshinone in the root culture of *Perovskia abrotanoides* [21]. The yields of atropine content in the *Datura metel* hairy roots were increased by nanosilver as an elicitor, after 12, 24 and 48 h of the treatment [22].

**Physical Elicitors:** Ultrasound, light, osmotic stress, salinity, drought and thermal stress are some of the physical elicitors.

**Ultrasound:** The low-energy ultrasound (US) also act as an abiotic elicitor to induce plant defense mechanism and stimulate the secondary metabolite production in plants [23]. In addition, US can induce cell membrane permeabilization so as to enhance intracellular product release. This cell-permeabilizing effect may be complementary to the two-phase culture to accomplish product release from the cells and removal from the medium. Lin and Wu [24] reported that, the combination of US stimulation and in situ solvent extraction in a *Lithospermum erythrorhizon* cell culture led to 2 to 3-fold increase in the yield of shikonin. While, in *Taxus chinensis* 1.5 to 1.8-fold increase in taxol yield with 2 minutes (min) US treatment once or twice during a week culture period was achieved [25]. In *Taxus baccata* cell culture the amount of taxol was increased by 3 times when treated with US [26], and ginsenoside saponins enhanced by 75% in *Panax ginseng* cell culture [27].

**Light:** The light is a physical factor which can affect the metabolite production in plants. Light can stimulate secondary

---

metabolites include gingerol and zingiberene production in *Zingiber officinale* callus culture [28]. Light plays a role in both growth and secondary metabolite production in the hairy roots. Sauerwein et al. [29] found that the alkaloid content of both normal and hairy roots of *Hyoscyamus albus* was greater in roots grown in the light compared to roots grown in the dark. The study of Yu et al. [30] in *P. ginseng* hairy roots also showed that the exposure of hairy roots to different light spectral ranges affected growth and metabolite biosynthesis. The light induced the growth as well as indole alkaloid production in the hairy root cultures of *Catharanthus roseus* [31]. The effect of light irradiation influenced artemisinin biosynthesis in hairy roots of *Artemisia annua* [32].

Ultrasound (UV) light acts as an abiotic factor which stimulates the biosynthesis of secondary metabolites [33]. UV radiation is divided into three regions: UV-C (wavelengths below 280 nm), UV-B (280-315 nm) and UV-A (315-400 nm). UV-C is the most damaging, but it is almost completely absorbed by the stratosphere. By contrast, UV-B radiation is only partially absorbed by the stratospheric ozone layer and UV-A is not at all absorbed. UV-B radiation was exclusively seen as a stress factor. UV-B trigger distinct changes in the plant's secondary metabolism resulting in an accumulation of phenolic compounds such as flavonoids and glucosinolates [33]. UV-B irradiation induced a rise of nitric oxide (NO) production, activities of nitric oxide synthase and phenylalanine ammonia lyase (leading to flavonoid synthesis), as well as flavonoid level in *Ginkgo biloba* callus [34]. Ramani and Jayabaskaran [35] reported enhanced catharanthine and vindoline production in suspension cultures of *C. roseus* by UV-B light. UV-B elicited an increase in the total terpenoid indole alkaloids (TIAs) concentrations in *C. roseus* hairy roots [36]. High doses of artificial UV-B radiation modified the antioxidant content by increasing the content of vitamin C and decreased the phenolic content of in vitro cultured *Turnera diffusa* plants [37]. Ku et al. [38] reported that synthesis of resveratrol and piceatannol were promoted by UV-C radiation in callus cultures [37]. Ku et al. [38] reported that synthesis of resveratrol and piceatannol were promoted by UV-C radiation in callus cultures [37].

**Osmotic, Salt and Drought Stress:** Osmotic stress is an important abiotic elicitor affecting plant growth, development, morphogenesis and the formation of secondary metabolites [41]. Sucrose is a typical osmotic stress agent used for the induction of water stress in plants that also serves as a vital carbon and energy source. The influence of osmotic stress enhanced the accumulation of capsaicin in callus suspension cultures of *Capsicum chinensis* [42]. It also enhanced the production of stevial glycosides content in both callus as well as suspension culture of *Stevia rebaudiana* [43].

Plants have developed complex mechanisms for adaptation to the osmotic, ionic and oxidative stresses that are induced by the salt stress. Exposure to salinity is known to induce or stimulate production of secondary plant products, such as phenols, terpenes and alkaloids [44,45]. The salt stress decreased the anthocyanin level in the salt-sensitive species [46]. The effect of KCl and CaCl₂ induced stress on in vitro cultures of *Bacopa monnieri* enhanced the accumulation of medicinally important bacoside A content [47]. An improved synthesis of vinblastine and vincristine was observed in *C. roseus* embryogenic tissue culture by using sodium chloride (NaCl) as an elicitor [48]. In *Nitraria tangutorum* suspension the increased sitosterol content was observed at 250 mM NaCl treatment [49]. Small increase of the canavanine content in *Sutherlandia frutescens* in vitro shoot culture growing on 100 mM NaCl medium was detected, indicating that salinity stress was not a major limitation on canavanine production [50].

The drought is an important stress factor limiting the plant growth, reproductive development and finally survival. Drought stress tolerance is seen in all plants, but its extent varies from species to species. Plants which are exposed to drought stress frequently were affected the synthesis and accumulation of secondary metabolite contents [51]. A weak water deficit greatly increased the glycyrrhizic acid content in roots of *Glycerrhiza uralensis* [52]. The drought stress was induced by polyethylene glycol (PEG), when it was treated to in vitro grown date palm callus, the proline content was increased gradually in response to increasing PEG-concentration. At higher concentration (30%) accumulation of proline started to decline as an indication of disturbance of physiological system [53]. PEG as a supplement had little to no effect on canavanine synthesis in *Sutherlandia frutescens* in vitro shoot culture [50].

**Thermal Stress:** Extreme temperature is an adverse environmental factor limiting growth and productivity of plants, it also hinders the plant growth by manipulating various metabolic processes including synthesis and degradation of primary metabolites [54]. Temperature range of 17–25°C is normally used for the induction of callus tissues and growth of cultured cells [6]. The *Melastoma malabathricum* cell cultures incubated at a lower temperature range (20 ± 2°C) grew better and had higher anthocyanin production than those grown at 26 ± 2°C and 29 ± 2°C [55]. Optimum temperature (25°C) maximizes the anthocyanin yield as demonstrated in cell cultures of *Perilla frutescens* [56] and strawberry [57]. Although temperature around 25°C is normally used for hairy root cultures, lowering the cultivation temperature (19.5°C) increased the proportion of linolenic acid and the total content of indole alkaloids in *C. roseus* hairy roots [58]. A 5°C increase in temperature significantly increased the ginsenoside content in roots of *Panax quinquefolius* [59].

**Hormonal Elicitors:**

**Salicylic Acid:** Salicylic acid is one of the most important abiotic elicitor, which has the capability to induce the secondary metabolites from in vitro cultures. SA induced the stilbene production in the cell suspension of *V. vinifera* [40]. A high concentration of 200 μM SA was required to induce substantial quantities of gymnemic acid in the suspensions that reached a maximum after 48 h treatment. The SA induced response towards gymnemic acid accumulation resulted in a 4.9-fold.

---

increase in comparison to the control cultures [60]. In the cell culture of <i>S. miltiorrhiza</i>, the different concentrations of the SA were affected the accumulation of salvianolic acid B and of caffeic acid. Both phenolic acid accumulations were significantly increased at 8 and 96 h after the applications of 3.125–25 mg/L of SA, but were significantly less with 32-50 mg/L of SA. After the 96 h treatments with 3.125–25 mg/L of SA, the concentration of the phenolic acids decreased significantly compared to the amount 8 h after the treatments, but were still higher than that of the control [61]. SA with transgenic technology, highly enhanced the production of tannines in <i>S. miltiorrhiza</i> hairy roots [62]. Optimum production of withanolide A, withanone and withaferin A were reported in the elicited-hairy roots of <i>Withania somnifera</i> [63].

**Jasmonates:** Jasmonic acid has been proposed as key compounds of the signal transduction pathway involved in the elicitation of secondary metabolite biosynthesis which takes part in plant defense reactions [64]. The application of a two-stage culture system with a combined treatment of mannitol (2mM) and JA (40μM) resulted in the optimum accumulation of resveratrol in the callus biomass of <i>V. vinifera</i> [65]. JA and its more active derivative MeJA can trigger the production of a wide range of plant secondary metabolites such as rosmarinic acid, terpenoid indole alkaloid and plumbagins in various cell cultures [66-68]. JA and MeJA have been used as elicitors for stilbene biosynthesis in <i>V. vinifera</i> cell cultures [69,70]. The treatment of MeJA to <i>V. vinifera</i> cell cultures also promoted anthocyanin accumulation [71]. In the cell culture of <i>Andrographis paniculata</i>, the MeJA induced the optimum accumulation of andrographolide at 24 h compared with 48 and 72 h of treatments [72]. In the <i>V. vinifera</i> cell system, a rapid accumulation of trans-resveratrol was recorded with MeJA treatment, starting from 2 h and reaching its maximum value at 96 h [70].

In a study, JA elicitation is reported to enhance the production of plumbagins in hairy root culture of <i>Plumbago indica</i> [73]. JA and MeJA have been used as elicitors for stilbene biosynthesis in <i>Vitis rotundifolia</i> hairy root cultures [74]. MeJA with transgenic technology, highly enhanced the production of tanshionines in <i>S. miltiorrhiza</i> hairy roots [62]. In the hairy root culture of <i>W. somnifera</i>, MeJA elicited the production of withanolide A, withanone and withaferin A [63]. The root cultures of <i>Taverniera cuneifolia</i> treated with different concentrations of MeJA, the glycyrrhizic acid content increased gradually with an increase in MeJA (1-100 μM) concentration. Approximately 2.5-fold elevation in glycyrrhizic acid production was noticed in MeJA (100 μM) treated roots, when compare to the control. However, further increase in MeJA (1000 μM) concentration resulted in the decrease of glycyrrhizic acid production [75]. The MeJA enhanced the production of bacoside A, a valuable triterpenoid saponin having nootropic therapeutic activity in <i>in vitro</i> shoot cultures of <i>B. monnieri</i> [76].

**Conclusion**

The evolutionary process made plant to produce new bioactive compounds time to time. The plant produces a number of secondary metabolites in varying concentration in different parts of the tissue. For more than three decades an <i>in vitro</i> culture plays an important role in the production of secondary metabolites from the particular tissue, organ and cells. In the past, less attention was paid to abiotic elicitor, but now the use of abiotic elicitors has emerged as one of the most effective strategy for enhancing the productivity of different commercial secondary metabolites from <i>in vitro</i> cultures. Though, elicitation enhances secondary metabolism in <i>in vitro</i> culture of plant cells/organ, but the exact mechanism of elicitation is still not fully understood. Moreover, molecular and biosynthetic pathway of the secondary metabolites should be understood and extensive research must be carried out in this way to determine the optimum conditions for each specific medicinal plant to enhance the secondary metabolites.
