Abstract

The mini review is depicted a role of vascular endothelial growth factor (VEGF) family members in strategy of clinical outcome suggesting among patients with acute ST segment elevation myocardial infarction (STEMI). Recent studies have shown that high levels of circulating VEGF in STEMI may characterize patients with extensive intracoronary thrombosis, as well as it could associate with favorable clinical outcomes. Although there was evidence about embedding of VEGF-A in a regulation of angiogenesis and vasodilation, pre-clinical and clinical studies have shown an ability of VEGF-A to up-regulate an expression of cell adhesion molecules, permeability, and inflammation in vascular wall. Yet, exon 8 of VEGF-A gene is involved in the alternate splicing that determines whether the VEGF-A proteins are pro-angiogenic isoform or antiangiogenic isoform of VEGF-A. Moreover, anti-angiogenic potency of VEGF-A165b isoform can influence on developing of adverse cardiac remodeling and plaque rupture. In the review is reported that predictive value of VEGF family member predominantly VEGF-A needs to be investigated in future, because there are several controversial in interpretation of changes in VEGF levels in STEMI.

Keywords: Vascular Endothelial Growth Factor; Acute ST Segment Elevation Myocardial Infarction; Endothelium; Prognosis

Introduction

Vascular endothelial growth factor-A (VEGF-A) is defined as important angiogenic factor which was found to be up-regulated in acute ST segment elevation myocardial infarction (STEMI) [1]. Circulating VEGF levels in patients with STEMI were significantly higher than in healthy volunteers and it has been demonstrated dramatically decreasing after successful reperfusion with percutaneous coronary intervention [2]. Although VEGF-A mediated angiogenesis and vasodilation, it was able to promote expression of cell adhesion molecules, such as E-selectin, intercellular adhesion molecule-1, and vascular cell adhesion molecule-1 VCAM-1 in surface of endothelial cells, and up-regulated permeability, pro-coagulant activity and inflammation of microvasculature [3]. Overall, there are serious controversies in the interpretation of VEGF dynamic in SEMI. The aim of the mini review is discuss the controversial role of VEGF family members in prediction of clinical outcomes in STEMI patients.

VEGF: definition

Vascular endothelial growth factor is determined as a family name of manifold factors contributing to angiopoetic effects [4]. In human VEGF-A, -B, -C, D- and placental growth factor (PGF) were identified [5], while other type of VEGF such as VEGF-E was also determined in the skin ushering in the Para poxvirus stimulation [6] and VEGF-F was isolated from Trimeresurus flavoviridis snake venom[7]. The main characteristics of VEGFs are reported in Table 1. Noted, all members of VEGF family mediate their biological effect via three types of VEGF receptors (VEGFR-1, VEGFR-1-2 and VEGFR-1–3), which sufficiently distinguished each other in appropriate co-receptors, neuropilins, and compounds of heparin sulfate proteoglycans [8]. The main trigger for VEGF-A production is hypoxia, which promotes synthesis of hypoxia-induced factor-alpha and thereby stimulate releasing of VEGF-A. VEGF-A triggers a migration of mononuclear / macrophages and induces angiogenesis / neovascularization, and vascular permeability [9]. Angiopoetic effect of VEGF-A associates with promoting endothelial progenitor cell proliferation, migration, and survival that leads to accelerating repair after injury. Therefore, VEGF-A stimulates functional activity of monocytes, fibroblasts and mesenchymal stromal cells. Additionally, exon 8 of VEGF-A gene is involved in the alternate splicing that determines whether the VEGF-A proteins are pro-angiogenic isoform or antiangiogenic isoform of VEGF-A [10]. VEGF-B and VEGF-C were found as specific promoters for embryonal angiogenesis as well as lymphangiogenesis and neurogenesis respectively [11-13]. VEGF-D is reported as a trigger for NO release, promoter of capillary-like tube formation and proliferation of endothelial cells

[14]. Placental growth factor (PIGF) is expressed in target cells during wound healing and mediates recruitment and migrating endothelial cells, keratinocytes and as well as monocyte [15]. Viral-expressed VEGF-E enhanced neo-epidermal thickness and wound re-epithelialization through increasing of the number of endothelial cells and blood vessels after binding with VEGFR-2 [16]. Unlike VEGF-A, VEGF-E did not promote expression and activity of matrix metalloproteinase (MMP)-2 and MMP-9, while increased expression of some anti-inflammatory cytokines, such interleukin (IL)-10, and reduced macrophage/mononuclear infiltration and myofibroblast differentiation in wounded skin [17].

**Expression of VEGF-A after myocardial infarction**

Previous studies have shown that vascular density begins steadily to increase immediately after myocardial infarction, peaks up at 7 day and then appears to be declined gradually [4, 18, 19]. Although peak levels of VEGF-A mRNA were found at the border zone in 2 hours after developing of myocardial infarction, there was a mishmash between VEGF-A mRNA expression and VEGF-A production. Noted, VEGF-A production in myocardial infarction was persistently suppressed for 12 hours, while over-expressed VEGF-A mRNA was determined for 2 days after event. Interestingly, the expression of VEGF-A both and VEGFR-1/2 remained unchanged in the non-infracted myocardium [20]. In fact, the hemodynamic parameters measured serially in peripheral blood were closely related to VEGF-A levels [18]. Therefore, lowered levels of VEGF-A can relate to altered angiogenesis in border zone around of necrotic core shaped after myocardial infarction and thereby mediate extension of the zone through inadequate blood flow reserve [20, 21]. Additionally, impaired angiogenesis, exageratory inflammatory and fibrotic responses due to deficiency of VEGF-A production plays pivotal role in worsening cardiac repair and scar tissue formation lading to adverse cardiac remodeling [22]. Apparently, hypoxia in border zone has to be a trigger for VEGF-A over-production, and extension of this zone could associated with lower levels of VEGF-A in circulation and VEGF-A mRNA in tissue, while clinical studies regarding developing of adverse cardiac remodeling after myocardial infarction have revealed controversial results, which are being poorly explained traditional approaches toward angiopoetic capacities of VEGF family members. Indeed, on the one hand, activating the VEGF signal cascade associated with increasing vascular permeability, disrupting endothelial tight junctions, promoting tissue edema, inducing thrombus formation, and inflammation. On the other hand, VEGF system activation leaded to hypocoagulation, angiogenesis, and neovascularization.

VEGF-A levels as predictor of clinical outcomes after myocardial infarction

Lowered levels of VEGF-A, VEGF-B and PlGF were recently emerged as a predictor of survival and cardiovascular risk in myocardial infarction patients [23-25], while increased levels of VEGF-A was found as predictor of intraluminal thrombi [25]. Interestingly, the main source for VEGF releasing after myocardial infarction is not fully verified. For instance, activated mononuclears were able to produce VEGF in border zone of infarction, on contrary, platelets were main source for VEGF releasing in the coronary artery wall [25]. Moreover, there were several mishmashes between angiographic figures, hemodynamic parameters after reperfusion and VEGF levels in peripheral blood. In fact, after acute ST segment elevation myocardial infarction (STEMI) increased circulating VEGF-A levels could reflect rather extending intracoronary thrombosis than adverse cardiac remodeling with poor clinical prognosis in follow-up. Recently it has turn out that clinical outcomes in patients after myocardial infarction with adverse cardiac remodeling associated with impaired ration between pro-angiogenic and angiogenic isoforms of VEGF-A [26, 27]. Moreover, the complexity and severity of coronary atherosclerosis and shaping of vulnerable atheroma related to predominantly increased expression of anti-angiogenic VEGF-A165b isoform in plaque and in circulation [27, 28]. Thus, circulating levels of VEGF-A165b are altered after myocardial infarction and might reflect the extent of cardiac damage. Probably, anti-angiogenic isoforms of VEGF-A can suppress migration differentiation and survival of endothelial progenitor cells, which are central players in endogenous vascular repair system [29]. Yet, it can suggest that pro-angiogenic and angiogenic isoforms of VEGF-B / VEGF-C could exist, because proximal / distal splicing is common for each member of the VEGF family. Otherwise it is so hard to explain that results of the ANOX Study. Indeed, in VEGF-C levels were significantly and inversely associated with all-cause death and cardiovascular death, but not with major adverse cardiovascular events (MACE) and cardiac remodeling [30]. Taking into consideration of origin of VEGF-C, MACEs have to be close related to concentration of the biomarker. Thus, changes in VEGF-C levels could reflect other causes related to outcomes in acute STEMI, for example, no-reflow phenomenon, intracoronary thrombosis, microvascular inflammation with further re-occlusion. In this context, large clinical trials are required to clear explain the possible role of VEGF family members in prediction of clinical outcomes in STEMI.

Conclusion

High levels of circulating VEGF in STEMI may characterize patients with extensive intracoronary thrombosis, else with favorable clinical outcomes. Therefore, anti-angiogenic potency of VEGF-A165b isoform can influence on developing of adverse cardiac remodeling and plaque rupture. In this context, predictive value of VEGF family member predominantly VEGF-A, VEGF-C and PlGF needs to be investigated in future, because there are several controversial in interpretation of changes in VEGF levels after STEMI.
