Submental fullness has been a concern for patients, Sonya Zarkhin, A 35-year-old female presented for evaluation of small sample size, lack of objective measures, Nwanneka Okwundu, Monica Huynh, Dimitria Papadopoulos, Open Access

Introduction

The chin and the neck have a significant contribution to the aesthetics of the face, hence any unconventional appearance of its features such as excess fat, may be bothersome to the patient[1-3]. According to a survey conducted by the American Society for Dermatologic Surgery (ASDS), 67% of the 7,315 respondents reported being “somewhat to extremely bothered” by excess fat under the chin or neck[4]. Over the years reduction of submental fat has been achieved with invasive surgical procedures such as liposuction, direct fat excision, and/or face/neck lift. However, due to the complications associated with invasive surgeries and their long recovery times, they are not a viable option for some patient populations[5-7].

A few non-invasive methods have been developed for the reduction of submental fullness. Noninvasive energy devices such as ultrasound or controlled cooling have been used for targeted destruction of subcutaneous fat cells. However, the techniques have not been rigorously tested and are not all currently optimized for submental contouring. The results have been variable and debatable as well[4]. In 2015, a new non-invasive method of submental fat reduction called Kybella was approved by the Food and Drug Administration (FDA). This drug has gone through decades of development and rigorous clinical trials. Kybella (Kythera Biopharmaceuticals, Westlake Village, California) is a first-in-class injectable agent approved for the reduction of submental fat[8,9]. It is a proprietary formulation of synthetic (nonanimal, nonhuman) deoxycholate that has gone through series of trials including 18-Phase 1 to 3 clinical studies to support the current indication, efficacy and safety. The significant improvement observed has also been correlated with objective improvement on magnetic resonance imaging[10,11].

Though Kybella treatment is non-invasive and its safety has been thoroughly tested, it is not without side effects. The most common adverse effects of Kybella are associated with the injection-sites. These adverse effects occur in at least 20% of patients and at a higher rate than with placebo. The treatment related adverse effects include edema, bruising, pain, numbness, erythema, and induration at the injection site, which sometimes lasts for more than 30 days. Marginal mandibular nerve injury (asymmetric smile, facial muscle weakness) occurred in 4% and dysphagia occurred in 2% of patients treated with the drug. All but one case resolved without treatment[7,12,13].
Different methods have been employed to alleviate these adverse effects including ice, NSAIDs, topical or injectable amides anesthetics, vibration, and botulinum toxin injection for pain reduction[4,14,15]. A small study showed that transdermal treatment with corticosteroids immediately after hyaluronic acid injections reduced swelling[16]. Hence, we utilized triamcinolone to alleviate the inflammatory effects of the Kybella injection and observed for changes in inflammatory response and patient outcome.

**Methods**

A 35-year-old female with a history of one previous treatment with Kybella greater than one year prior to office visit presented for evaluation of submental fullness. She elected for treatment of her submental fullness with deoxycholic acid. The intensity and laxity of submental fullness was evaluated by pinching and pulling. The patient was also asked to smile, swallow, and grimace to evaluate the platysma. The injection area was cleaned. Her submental treatment area marked for treatment was bounded superiorly by a line 1 cm inferior to the mandibular margin, laterally by the sternocleidomastoid muscles, and inferiorly by the hyoid bone and divided into right and left portions. Transfer paper with printed grid pattern was pressed on the side of her skin. Cotton ball soaked with sterile water was pressed firmly on it and the paper was peeled.

In the right submental treatment area, 2ml of deoxycholic acid 10mg/ml plus 0.2ml triamcinolone acetate 10mg/ml was mixed and then delivered in 13 injections spaced 1.0 cm apart at 0.2 mL/injection using a 30 gauge 0.5-inch needle. In the left submental treatment area, deoxycholic acid alone 20mg/2ml was delivered in 13 injections spaced 1.0 cm apart at 0.2 mL/injection. At the end, the grid marks were removed with alcohol. The patient was asked to swallow again to re-evaluate submental fullness. The patient was observed over duration of 3 months to evaluate inflammation and treatment response between the two treatment zones. The patient was brought in for re-evaluation at 4, 8, and 12 weeks.

The split-neck study resulted in decreased post-injection swelling. At 12-week follow-up, there was no clinical improvement to the submental fullness bilaterally. The patient did not show or report any side effect associated with topical triamcinolone use during the duration of observation(Figure 1-4).

**Discussion**

ATX-101 or deoxycholic acid injection (known as Kybella in the United States and Belkyra in Canada) was approved in 2015 as a first-in-class injectable drug for improvement in the appearance of moderate to severe convexity or fullness associated with submental fat[8,11]. The idea that led to the development of ATX-101 as a pharmacologic treatment for reduction of submental fat was identified by Rotunda and colleagues[11,17].

Deoxycholic acid is the primary mediator of adipocyte lysis in compounded phosphatidylcholine/sodium deoxycholate. When injected into submental fat, ATX-101 physically disrupts the adipocyte cell membranes and causes cell death as early as 1 day after injection. Subsequently neutrophils invade tissue (day 3), followed by macrophages (day 7), followed by fibroblasts (day 28). By one month, inflammation largely resolves, providing the rationale for the approved monthly intervals between each treatment. Relatively protein-poor tissue such as fat is more sensitive to the cytolytic effects of deoxycholic acid than relatively protein-rich tissues such as skin and muscle[18,19]. Due to these properties, Kybella also has an off-label use to correct central abdominal fat, the "muffin top" or "love handle" abdominal fat overhang, lipomas, buttock fat, thigh fat, upper-arm fat, cellulite, and infraorbital fat pads.
Kybella has not been found to affect the internal homoeostasis of the body. ATX-101 is rapidly absorbed when injected subcutaneously into either submental fat or abdominal fat in healthy subjects. Phase I studies have shown that when ATX-101 is subcutaneously injected into fat, plasma levels of deoxycholic acid rapidly increases, remains within the physiologic range for endogenous deoxycholic acid, and then returns to baseline levels within 12 to 24 hours[20,21]. In addition, these Phase 1 studies have shown that ATX-101 has no clinically meaningful effect on heart rate, QT/QTc intervals on electrocardiography, or plasma concentrations of total cholesterol, triglycerides, low-density lipoprotein, high-density lipoprotein, free fatty acids, or proinflammatory cytokines[21]. Rather, fluctuations observed in total cholesterol, triglyceride, and free fatty acid levels after ATX-101 administration were short lived as compared to those observed after ingestion of a meal. Furthermore, all liver and renal function laboratory values were found to be unremarkable[11]. Although, Kybella injections may not alter the internal homoeostasis of the body, they are associated with injection site adverse effects. In a study conducted by the United States Food and Drug Administration (FDA), the patients receiving the active drug had the following side effects: edema/swelling (87%), hematoma/bruising (72%), pain (70%), numbness (66%), erythema (27%), induration (23%), and temporary marginal mandibular nerve dysfunction resulting in an asymmetric smile (4%). In the placebo group of this study, the only comparable adverse event to the active drug Kybella was bruising at 70%[9,11,22]. Fortunately, the injection-site reactions observed in these clinical trials are mostly mild or moderate and transient[22]. Furthermore, the incidence and severity of these adverse effects were also found to decrease after the first treatment[10,23]. It was also observed that in ATX-101–treated subjects, peak pain occurred within 1 to 5 minutes of treatment. Most patients reported mild and substantially reduced pain by 15 minutes[24]. Consequently, some studies have attempted different methods of alleviating these adverse effects. In a double-blind, parallel-group, 2-factor, single treatment, exploratory phase 3b study, subjects were randomized to 1 of 4 patient experience management paradigms (cold, cold+anesthetic+epinephrine; cold+anesthetic+epinephrine+Antihistamine+NSAID; and cold+anesthetic+epinephrine+Antihistamine+NSAID+ch.in strap). It was observed that adding
