Abstract
Cytomegalovirus (CMV) is a DNA virus belonging to the herpesvirus group. The infection from this virus is increasing in the immune compromised patients, especially AIDS or organ transplant recipients. Nevertheless, the skin lesion is uncommon. We present two cases of atypical cutaneous CMV infection.

The first case was a 66-year-old Thai woman with overlapping syndrome, on treatment with multiple immune suppressants. She presented with high grade fever and asymptomatic purpuric papules and pustules on her forearms and legs. Laboratory investigations showed bicytopenia from complete blood count. Chest radiography and high-resolution computed tomography of the chest revealed lung nodules.

The second case was a 49-year-old Thai woman with Systemic Lupus Erythematosus (SLE) and obtained multiple immune suppressants. She presented with fever and multiple erythematous papules with ulcers of the extremities and trunk. Basic laboratory investigations were normal.

The skin biopsies from both cases showed perivascular infiltration with inflammatory cells and numerous large round eosinophilic intranuclear inclusion bodies (owl's eye appearance) in the dermis. The CMV antigen stained the cytoplasm of owl's eye cells.

Further investigations presented high level CMV viral load in both cases. The diagnosis CMV infection was made.

In conclusion, we presented the cases with cutaneous CMV infection in immune compromised host. This group of patients is susceptible to variety of infections and presented with atypical manifestations. Cutaneous manifestations with skin biopsy in some cases may play a major role for the correct diagnosis and prompt treatment.

Introduction
Cytomegalovirus (CMV) is a DNA virus belonging to the herpesviridae family. It is a common opportunistic infection in fetus, allograft and bone marrow transplant recipients and AIDS [1]. The infection was detected close to 100% in developing countries [1, 2]. The transmission occurs via body fluids (saliva, urine, blood, semen, vaginal secretion, breast milk) and also via transplant organs [2]. In the primary infection, CMV can infect many cell types and causes viremia, using blood leukocytes as transport medium [2, 3]. After the primary infection, CMV stayed latent lifelong in the hosts and rarely causes diseases in immunocompetent individuals [3].

Case reports
Case 1
A 66-year-old woman presented with high grade fever and fatigue for 1 month. Three weeks after the presence of fever, she developed asymptomatic skin rashes on the extremities. Her underlying disease was overlapped syndrome (rheumatoid arthritis with anti-phospholipid syndrome). Her conditions were controlled with methotrexate 15 mg/wk, hydroxychloroquine 200 mg/d, prednisolone 10 mg/d, leflunomide 20 mg/d, azathioprine 50 mg/d, rituximab 1000 mg/mo (total 2 dose), aspirin 81 mg/d and enalapril 40 mg/d.

Physical examination revealed 38.7°C body temperature. There were multiple ill-defined erythematous purpuric patches and pustules on the forearms and legs (Figure 1). Other examinations were unremarkable. She was diagnosed as active CMV infection.

Further laboratory investigations revealed anemia, lymphopenia and high CMV viral load (2,418,532 copies/ml). Chest x-ray showed reticulonodular infiltration in both lungs. The retinal examination from an ophthalmologist was normal.

She was diagnosed as active CMV infection. The treatment

Physical examinations showed 38.8°C body temperature. There were multiple well-defined erythematous crusted papules on her right arm, right forearm and abdominal wall with a solitary ill-defined erythematous papule with shallow ulcer and pustules on the right elbow (Figure 4, 5). Other examinations were unremarkable.

The skin biopsy form the ulcer revealed dense superficial and deep perivascular and interstitial infiltration composed of lymphocytes and histiocytes. Therewere vascular wall destruction with fibrinoid deposition and numerous large round cells with eosinophilic intranuclear inclusion bodies (owl's eye cells) in the endothelial cells (Figure 6). The immunohistochemistry for CMV antigen highlighted in the cytoplasm of owl's eye cells (Figure 7).

Further laboratory investigations showed anemia, lymphopenia and also high CMV viral load (2,624,532 copies/ml). The retinal examination from an opthalmologist was normal.

She was diagnosed as active CMV infection. The treatment was started with intravenous ganciclovir. After 8 weeks of the treatment, the lesions were resolved without any complication.

Discussion

CMV infection causes various dermatologic and systemic disorders but usually asymptomatic in immunocompetent hosts [3]. The most common clinical presentation is a mononucleosis-like syndrome resemble to EBV infection [2, 4].

In immunocompromised host, CMV infection presents as a wide variety of manifestations depending on the degree of immunosuppression which is a major cause of morbidity and mortality. This group of patients usually acquires disseminated CMV disease involving many organs, resulting to chorioretinitis, pneumonitis, gastrointestinal, Central Nervous System (CNS), renal, bone marrow and endocrine abnormalities [2, 5]. Nevertheless cutaneous involvement of CMV is a rare manifestation [5]. Genital ulcers are the most common skin lesions among the AIDS and non-AIDS, immunocompromised patients and usually accompany with polymicrobial infection, especially herpes simplex virus infection [6, 7]. Morbiliform eruptions, purpura, vesiculobullous lesions, nodules, papular eruptions, verrucous lesions and ulcers were also reported [2, 6].

The typical histopathology of tissues infected with cytomegalovirus shows characteristic cells with intranuclear and intracytoplasmic inclusion bodies (owl’s eye appearance) which was only limited to fully developed lesions [6, 8]. In early infection, the initial cellular change is cell enlargement with enlarged basophilic nucleus and prominent nucleolus. Then the cell continues to enlarge and the cytoplasm has smudged, amphophilic, bubbly quality. The fully developed change shows basophilic intranuclear and intracytoplasmic inclusion bodies. While the CMV infection resolves, the cell including the nucleus shrinks [6, 8]. The affected cells are mostly mesenchymal cells, especially endothelial cells. Fibroblasts, inflammatory cells, and rarely epithelial cells are less commonly affected [6, 8, 9].

Additional histopathologic features include leukocytoclastic

Figure 1: Clinical appearances of Case 1 presenting as purpuric patches and pustules on right thigh.

Figure 2: The section demonstrated large cells with eosinophilic intracytoplasmic and intranuclear inclusion bodies (owl’s eye cells) observed in the vascular endothelium in the dermis (H&E, x400).

Figure 3: The immunohistochemistry for CMV antigen highlighted in the cytoplasm of these owl’s eye cells.

Case 2

A 49-year-old woman presented with high grade fever and asymptomatic skin rashes for 3 weeks. She had underlying diseases as systemic lupus erythematosus (SLE) which was well controlled with mycophenolate mofetil 2 g/d, prednisolone 40 mg/d and chloroquine 250 mg/d. The typical histopathology of tissues infected with cytomegalovirus shows characteristic cells with intranuclear and intracytoplasmic inclusion bodies (owl’s eye appearance) which was only limited to fully developed lesions [6, 8]. In early infection, the initial cellular change is cell enlargement with enlarged basophilic nucleus and prominent nucleolus. Then the cell continues to enlarge and the cytoplasm has smudged, amphophilic, bubbly quality. The fully developed change shows basophilic intranuclear and intracytoplasmic inclusion bodies. While the CMV infection resolves, the cell including the nucleus shrinks [6, 8]. The affected cells are mostly mesenchymal cells, especially endothelial cells. Fibroblasts, inflammatory cells, and rarely epithelial cells are less commonly affected [6, 8, 9].

Additional histopathologic features include leukocytoclastic
Atypical Cutaneous Cytomegalovirus (CMV) Infections in Non-AIDS Patients; a Report of 2 Cases

vasculitis, eccrine squamous syringometaplasia, and neuritis [10-12]. The diagnosis of CMV vasculitis is made when there is evidence of vascular destruction (vessel wall damage, necrosis and luminal obstruction). CMV associated-vasculitis can occur in the internal organs, especially GI tract and central nervous system [13]. The vascular injury can be caused by either direct endothelial damage by virus, which usually shows the typical inclusion bodies in the endothelial cells or via induction of immune-mediated hypersensitivity [10, 13, 14]. Furthermore, cytomegalovirus neuritis was diagnosed by demonstrate the CMV inclusion bodies in the Schwann cells [12].

In addition to CMV infection in AIDS and transplant recipients, there were many reports of the association of CMV infection and connective tissue diseases.

In SLE, the increased risk of infections due to the prolonged use of immunosuppressants was mentioned. Ramos-Casals M, et al, showed that CMV was the most common viral infection in SLE [15]. CMV antibodies were detected in nearly 50% of SLE cases who presented with acute viral infection and the majority of the cases were Asian. [15]

The association of CMV infection and SLE is still unclear but may involve many factors. Active SLE induces immune reactivation which induces proliferation of immune cells, resulting in proliferation of latent CMV in the cells. In addition, immunosuppressive treatments may also allow the reactivation of latent virus [16-18]. In the contrary, CMV infection can also trigger the development and the flare of SLE [16, 17]. This group of patients presented with acute CMV infection and positive IgM anti CMV antibodies prior to the diagnosis of SLE [16-19]. The mechanism of CMV induced autoimmunity had not been fully clarified. The possible mechanism is the cross-reactivity between T-cell and CMV antigens in susceptible individual. [19-20]

CMV has been reported as a triggering factor of vascular damage in systemic sclerosis. [21] Moreover, CMV DNA specific antigens were detected in synovial tissue and fluid from rheumatoid arthritis joints in 10-50% of the patients, but the role of involving the disease is still unclear. [21-25]

The clinical manifestations of active CMV infection can also mimic the active SLE flare as seen in our cases with the presenting symptoms of fever, skin lesions resemble cutaneous vasculitis, lymphopenia and anemia [18]. The diagnosis of CMV infection was confirmed by the feature of CMV vasculitis in the skin biopsies and the elevated serum CMV viral load. The causative factors of CMV infection in our cases may be from prolonged immunosuppressants reactivated the latent CMV infection.

The first line treatment for CMV infection is intravenous ganciclovir, while oral valganciclovir is preferred for prophylaxis and preemptive therapy [26-28]. The second-line treatment is foscarnet which is limited to be used in ganciclovir-resistant CMV infection or in patients contraindicated to use ganciclovir. The third agent is cidoforvir which is limited to be used due to the presence of poor bioavailability and nephrotoxicity. [26]
Atypical Cutaneous Cytomegalovirus (CMV) Infections in Non-AIDS Patients: a Report of 2 Cases

In conclusion, we reported two cases of active CMV infections who presented with non-specific skin lesions. Both cases had underlying connective tissue diseases, controlled with multiple immunosuppressants. The clinical presentation of CMV infection can mimic flare of the underlying diseases. The careful physical examinations and proper investigations are keys for the diagnosis and prompt management.
