Abstract

Background/Aims: To compare mortality and cardiovascular risk in elderly dialysis patients with diabetes under two clinical strategies of anemia correction: maintaining hematocrit (Hct) between 34.5 and <39.0% (high Hct strategy), and between 30.0 and <34.5% (low Hct strategy) using intravenous alpha epoetin.

Methods: Observational data were used to emulate a randomized trial in which diabetic patients who initiated hemodialysis in 2006-2008 were assigned to each anemia correction strategy. Inverse-probability weighting was used to adjust for measured time-dependent confounding.

Results: Comparing high with low hematocrit strategy, the hazard ratio (95% confidence interval) was 1.07 (0.83, 1.38) for all-cause mortality and 1.00 (0.81, 1.24) for a composite mortality and cardiovascular endpoint.

Conclusions: Among a cohort of elderly hemodialysis patients with diabetes, no differences were found between the low and high hematocrit strategies. A lower target hematocrit - per current Food and Drug Administration (FDA) guidelines - appears to be as safe as higher targets among this population.

Introduction

Morbidity and mortality rates for persons with diabetes and chronic kidney disease (CKD) in the US are high [1,2]. One potential area for improvement of patient survival is the management of anemia, the most common complication among dialysis patients. Yet, twenty years after the introduction of erythropoiesis-stimulating agents (ESA; including epoetin, epoetin alfa, and darbepoetin) to treat anemia, there is still considerable uncertainty in the nephrology community regarding an optimal hematocrit target among dialysis patients with diabetes as a comorbid condition [3-5]. We conducted an observational analysis of elderly dialysis patients with diabetes to compare their mortality and cardiovascular risk under two clinical strategies of

anemia correction: maintaining hematocrit (Hct) between 34.5 and <39.0% (high Hct strategy), and between 30.0 and <34.5% (low Hct strategy) using intravenous alfa epoetin.

Research design and methods

We used the same source population and methods that we have previously employed to compare these two strategies in patients with diabetes and cardiovascular disease [6]. In this paper, for the first time, we present results for patients with diabetes regardless of cardiovascular disease. Only one other clinical trial, the Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT), [7] examined epoetin use among chronic kidney disease patients with diabetes but our study differs and is novel in two important ways: 1) TREAT enrolled predialysis patients while our study includes end-stage renal disease (ESRD) patients; and 2) TREAT evaluated a near normal hematocrit value (>39%) versus placebo while our study compared the Food and Drug Administration (FDA)-recommended strategy of hematocrit <33% with the commonly used strategy of hematocrit 34-39%.

We emulate a randomized trial by using observational data from the United States Renal Data System (USRDS), which includes the universe of US dialysis patients. We identified incident hemodialysis patients with diabetes who were 65 years and older and received their first ESRD service in 2006-2008. The inclusion criteria were age 65 years or older and evidence of diabetes after 3 months on dialysis. The exclusion criteria were: history of cancer prior to ESRD (studies suggest that patients with cancer might respond differently to epoetin therapy[8,9]), no epoetin therapy in the first 30 days of outpatient dialysis, kidney transplantation or use of peritoneal dialysis modality or darbepoetin (a derivative form of epoetin used primarily in inpatient settings) before baseline, hematocrit <24% at baseline, incomplete baseline covariate values, baseline data inconsistent with the strategies of interest, patients who did not reach hematocrit of 30% at baseline (non responders), or follow-up started in a nondialysis facility (Supplemental Figure 1). A patient was classified as 'diabetic' if diabetes was reported

to be the primary cause of renal failure and/or diabetes was listed as a co-morbid condition on the Medical Evidence Form 2728 which is completed when a patient enrolls in the Medicare ESRD program. Follow-up started after completing 3 months of hemodialysis therapy (baseline) and ended at the time of first endpoint, death, potential data errors, or loss to follow-up (30-day gap in outpatient dialysis or inpatient claims); which ever happened first, or six months after patient entry.

The two endpoints of interest were all-cause mortality and a composite outcome including death or hospitalization for myocardial infarction (MI), stroke or congestive heart failure (CHF), as identified by International Classification of Diseases (ICD)-9 codes on Medicare hospital claims. These outcomes are similar to those used in two recent epoetin randomized trials [10,11]. Data on hematocrit and epoetin therapy were obtained from claims for dialysis services submitted by the dialysis facilities for payment by Medicare. Potential confounders were sociodemographics, body mass index, severity of illness and comorbidities (e.g., cerebrovascular disease, chronic obstructive pulmonary disease), amputation, inability to ambulate, receipt of parenteral iron therapy), dialysis facility characteristics, and predialysis use of ESA therapy. All variables included in this study are listed in Table 1.

We emulated the “per protocol” analysis of a randomized clinical trial that compares the high Hct and low Hct strategies if all subjects had adhered to their baseline strategy throughout the entire follow-up. We classified eligible USRDS patients as following one or both of the following strategies: High Hct Strategy: intravenous epoetin alfa to achieve and maintain hematocrit values of 34.5-<39.0% or Low Hct Strategy: intravenous epoetin alfa to achieve and maintain hematocrit values of 30.0-<34.5%. Under both the strategies, monthly epoetin dose is changed according to the following rules:

- If previous hematocrit is below the target range, epoetin dose is increased by $\geq 10\%$;
- If previous hematocrit is within target range, epoetin dose is decreased by $<10\%$ times [hematocrit minus lower end of range] or increased by $<10\%$ times [upper end of range minus hematocrit];
- If previous hematocrit is above the target range, epoetin dose is decreased $\geq 25\%$ or withheld.

The administration of IV iron during the month after the patient undergoes hemodialysis in a facility not participating in the study (e.g., hospital, hospice, nursing home or home health services) and after epoetin dose was withheld, is left to the discretion of the treating physician. We could not directly evaluate the FDA recommended strategy (target Hct<33%) because only a few patients were treated under this strategy during the study years.

For each month of follow-up, if a patient’s data were consistent with both strategies (for example, a patient with hematocrit <30% whose epoetin dose was increased by $>10\%$), we created an exact copy of the patient’s data for each strategy [12]. Patients assigned to a strategy were artificially censored when their treatment data ceased to be consistent with that strategy.

Because higher epoetin doses are more likely to be prescribed to patients with lower hematocrits who also might be at higher mortality and cardiovascular risk, the estimates from our model needed to be adjusted for the effect of time-dependent confounding by indication [13]. In other words, a technique is needed that addresses the issue of confounding by indication; i.e., whether higher epoetin doses correlate with higher Hct levels or more epoetin resistance and lower achieved Hct levels - a conundrum affecting nearly all observational studies using conventional statistical techniques which adjust for confounding

Figure 1: Adjusted survival curves and hazard ratios of death (left column) and composite endpoint (right column) for High (34.5-<39.0%) versus Low (30.0-<34.5%) Hematocrit Target Treatment Strategies among diabetic patients undergoing hemodialysis using IP-weighted model, United States Renal Data System, 2006-2008. HR=hazard ratio; CI=confidence interval.

^c Includes amputation, inability to ambulate, and inability to transfer.

factors at baseline only. As previously described, [14] we used inverse probability (IP) weighting to adjust for time-dependent confounding by measured time varying covariates including hematocrit, iron treatment, and hospitalization. Specifically, in contrast to more traditional statistical techniques that cannot

handle time-dependent confounding and sometimes result in spurious findings, IP results tend to more closely approximate the risks or benefits of an intervention both in terms of direction and magnitude of hazard ratios [15-20].

When the outcome of interest was death only, we also adjusted the model for hospitalization due to CHF, MI, and stroke. Each patient received a time-varying weight inversely proportional to the estimated probability of having his/her own observed epoetin dose history. Specifically, we used stabilized IP weights to adjust for selection bias due to artificial censoring discussed above [21]. We truncated the weights to a maximum value of 20 (with a mean of 1.1 and standard error of 2.5) for statistical efficiency. Finally, we estimated the survival curves under each treatment strategy by using the predicted values of weighted outcome models that included an indicator for treatment strategy, baseline covariates, month of follow-up (cubic splines), and product ("interaction") terms between the treatment strategy indicator and the month variables. Point-wise 95% confidence intervals for all parameter estimates were calculated via percentile-based non-parametric bootstrap based on 300 full samples. Separate analyses were conducted after including patients who did not reach hematocrit of 30% at baseline (non responders). All analyses were conducted with Statistical Analysis System (SAS) 9.1 (SAS Institute, Cary, NC).

Results

Of 112,449 elderly dialysis patients who initiated epoetin treatment between January 2006 and December 2008, 29,232 patients met the study eligibility criteria. Of 17,291 (59.2%) who were diabetic, 3,637 were classified in the Low Hct strategy only, 5,390 in the High Hct strategy only, and 8,264 in both. There were no important differences between Low Hct and High Hct patients in patient characteristics or dialysis facilities in which they received care. During the 6-month follow-up, there were 467 deaths (643 composite events) under the Low Hct strategy and 766 deaths (1,048 composite events) under the High Hct strategy. We estimated no difference (0.0%) in absolute 6-month survival or composite endpoint between the High Hct and Low Hct strategies (Figure 1). The hazard ratios (HRs) (95% CI) for the High Hct vs. Low Hct strategy were 1.07 (0.83, 1.38) for death and 1.00 (0.81, 1.24) for the composite event (Figure 1). Patient results are provided in a supplemental electronic appendix.

Conclusions

Using observational data, we emulated a randomized trial of elderly dialysis patients with diabetes assigned to either a high range hematocrit target (34.5-39%) or a low range (30-34.5%) treatment target. We found no differences in the rates of mortality or the cardiovascular composite between these two clinical strategies.

Our study addressed questions left unanswered by TREAT, a recent randomized trial of diabetic CKD predialysis patients [7] This trial found no cardiovascular or renal benefits and an increased stroke risk for those assigned to a target hematocrit level of 39% compared with those assigned to rescue treatment for hematocrit levels <27%. However, TREAT enrolled

predialysis diabetic patients and therefore the generalizability of their findings to the dialysis populations is uncertain. Our study included *ESRD dialysis* patients with diabetes. Second, the 4,038 person TREAT trial was not designed to ascertain the optimal hematocrit range and therefore this question remains unanswered. Last, the TREAT investigators themselves suggest that it is possible that other dosing strategies could be developed to mitigate the risks found in their study that targeted a hematocrit of 39%, while conserving the modest benefits of treatment.

In this research, we used the largest observational data available for ESRD research and appropriate analytic methods to handle time-varying treatments and confounders from complex longitudinal administrative data. There are, however, important study limitations. First, the validity of our estimates depends on the assumption that all confounding factors were correctly measured and included in the model [22]. Since epoetin treatment was not randomized, residual confounding could still remain. Second, our analytic method relies on artificial censoring of patients who deviate from their baseline strategy and thus constrained the analysis to a shorter follow up than TREAT. Finally, study results suggesting that a higher hematocrit target does not confer any additional benefits among elderly hemodialysis patients with diabetes is limited to the following population: patients without a history of cancer, previous renal transplant, or severe anemia (Hct < 24%) at dialysis initiation, who were not hospitalized for stroke, congestive heart failure or myocardial infarction in the first 3 months of dialysis, and who were deemed responders to epoetin therapy (achieving a hematocrit of 30% at baseline) (Supplemental Figure 1).

Previous randomized trials of epoetin therapy - three in predialysis chronic kidney disease patients, [7,10,11] and one in dialysis patients [23] found increased mortality or no benefits for near normal hematocrit targets. As a result of the randomized trial findings, in June 2011, the FDA changed the labeling of ESAs and recommended that physicians "reduce or interrupt the dose" of epoetin if hematocrit exceeds 33% among dialysis patients. Given the lack of benefits associated with the higher hematocrit target, our study findings support the most recent FDA advisory for dialysis patients with diabetes.

Supplemental Electronic Index

Inclusions

112,449 elderly patients initiated outpatient dialysis within 90 days of enrolling in the Medicare ESRD Program in 2006-2008

Exclusions

- 12,173 had cancer before ESRD
- 17,054 received no epoetin within first 30 days of dialysis
- 5,133 had kidney transplantation or peritoneal dialysis before baseline
- 890 used darbepoetin before baseline
- 1,270 patients had hematocrit <24% at baseline
- 10,171 had hospitalization due to MI, CHF, and stroke before baseline
- 8,892 had >2 days of inpatient stay in last month before baseline
- 11,893 patients had <11 dialysis sessions in the last month before baseline
- 111 patients had incomplete baseline data
- 5,408 patients identified as poor responders at baseline
- 9,535 had baseline data inconsistent with strategies of interest
- 687 started follow-up in a nondialysis facility (e.g., hospital).

29,232 eligible patients
