Abstract

Prevalence of Type 2 Diabetes Mellitus (T2DM) is increasing along with obesity rates. Novel approaches are necessary to prevent this deadly pathology and its associated morbidity & mortality. Recent evidence suggests that very low calorie diet (VLCD) in selective adult T2DM patients, under close supervision, reaps benefits. In this mini-review, we have discussed the relevant literature on VLCD in the context of T2DM.

Introduction

Type 2 diabetes mellitus is a metabolic disorder resulting from a combination of insulin resistance and insulin deficiency [1]. It's prevalence has been increasing in epidemic proportions and the global prevalence in adults was quoted to be 8.5% in 2014 [2]. The first WHO (World Health Organisation) global report on diabetes, which was published in 2016, demonstrated that the number of adults living with diabetes had almost quadrupled since 1980 to 422 million [3]. It is the fifth largest cause of death globally [4]. An aging population, increasing level of obesity in combination with decreased physical activity and poor diet/lifestyle are the major contributing factors [2].

Among the patients with diabetes, 85-95% have T2DM and it has a huge cost implication on any healthcare system [1]. A study from United Kingdom (UK) estimated that the annual cost of the direct patient care of diabetes in the UK will increase from £9.8 billion to £16.9 billion over the next 25 years, lion share of which was attributed to T2DM (£1 billion for type 1 diabetes and £8.8 billion for type 2 diabetes currently) [5].

There is close relationship between T2DM and obesity [6]. For every 1 kg weight gain, there is a 9% increase in relative risk of developing T2DM [7]. Metabolic abnormalities associated with T2DM including hyperglycaemia, dyslipidaemia, obstructive sleep apnoea and hypertension are also associated with worsening obesity [8].

Weight reduction plays an important role in the prevention and treatment of T2DM as it improves glycaemic control by reducing the insulin resistance and also has a positive impact on cardiovascular morbidity and mortality [2]. However, long-term non-pharmacologic weight loss interventions for adults with T2DM have shown limited efficacy because of regain of the initial weight loss [2,9]. Henceforth, alternative weight loss strategies that are safe and effective are required [10].

Diets that are generally used to control blood glucose levels include low fat and high unrefined carbohydrate (those which take around 25-30% of energy from fat and around 50% of the total energy from unrefined carbohydrate), or low glycaemic index diets (i.e. oats, beans, fruits & vegetables) usually in conjunction with exercise. In the absence of significant number of long term interventional trials [11] and taking into consideration of the prevalence of T2DM and its potentially serious outcomes, it is important to establish which type of diet, either alone or in combination with other interventions (the addition of exercise, behavioural approaches and alternative treatments), is most effective [1].

A series of recent studies have shown that with a calorie-restricted diet, the reversal of T2DM is possible in selected patient groups[12]. It is believed that VLCD reduces systemic inflammation and oxidative stress by modulating inflammatory cytokines and adipokines thus resulting in improved beta cell function, decreased hepatic gluconeogenesis and reduction in visceral fat. Henceforth, the usage of VLCD in T2DM patients is progressively becoming popular in view of potential holistic improvement in cardio-metabolic health [13-16]. Indeed, this can be compared with the glycaemic improvement after bariatric surgery [17].

Mechanism of action of VLCD and related evidence

A very low calorie diet is defined as a diet of less than 800 kilocalories (kcal) per day [18]. In VLCD, intake of fat and carbohydrates is reduced but protein intake is maintained (0.8
g/kg ideal bodyweight per day) which promotes lipolysis and ketosis while preventing a negative nitrogen balance, thus sparing lean body mass [19]. Fasting plasma glucose levels become normal within days because of a rapid reduction in hepatic fat and normalisation of hepatic insulin sensitivity. Variety of other mechanisms were proposed including reduction in hepatic glycogenolysis and gluconeogenesis. Reduction in pancreatic fat leads to improvement in β-cell function resulting in restoration of first phase insulin response post-prandially to non-diabetic levels [11, 13, 15]. If the normalisation of hepatic insulin sensitivity and β-cell function could be maintained in the longer term, this could change the entire approach to T2DM management [12] albeit in selected group of patients.

The commonly used VLCD’s are commercially available mixed-formula diets, containing various amounts of carbohydrate, fat and high quality protein, and they have proven safety for use in patients with T2DM [19, 20]. In Australia, New Zealand, Singapore and Hong Kong, VLCD products are typically available over the counter and do not require a prescription. Newer VLCD products contain all the essential amino acids, micronutrients thus avoiding related nutritional deficiencies.

The Newcastle Counterpoint study [11] achieved reversal of T2DM with mean weight loss of 15.3kg in 11 people with T2DM (duration < 4 years since diagnosis), using a 600 kcal per day low-energy liquid diet. The normalisation of fasting plasma glucose persisted for up to 3 months after return to normal diet [21]. In addition, acute energy restriction has been shown to improve plasma glucose values and insulin sensitivity even before significant weight loss occurred [11, 22].

In a 6 months weight stability study in T2DM in 30 patients following 8 weeks of VLCD, 40 % of participants achieved a fasting blood glucose of <7 mmol/L after 6 months of returning to isocaloric diet. The mean weight loss was 2.5 kg but most of the responders had shorter duration of diabetes and had received structured individualised weight maintenance advice [12].

In DiRECT trial (Diabetes Remission Clinical Trial) which assessed the remission of diabetes with a primary care led weight management programme showed 46% (n=68) of the participants in the intervention group achieved remission at one year. Around 25% (n=36) of the participants lost at least 15 kg of weight. At 24 months, 35.6% (53/149) of those in the intervention group remained in remission compared to 3.4% (5/149) in the control group. The adjusted mean difference in body weight change in between the control and intervention groups was −5.4 kg (95% CI −6.9 to −4.0; p<0.0001) and in HbA1c was −4.8 mmol/mol.

Around 25% (n=36) of the participants lost at least 15 kg of weight. At 24 months, 35.6% (53/149) of those in the intervention group remained in remission compared to 3.4% (5/149) in the control group. The adjusted mean difference in body weight change in between the control and intervention groups was −5.4 kg (95% CI −6.9 to −4.0; p<0.0001) and in HbA1c was −4.8 mmol/mol.

In a 6 months weight stability study in T2DM in 30 patients following 8 weeks of VLCD, 40 % of participants achieved a fasting blood glucose of <7 mmol/L after 6 months of returning to isocaloric diet. The mean weight loss was 2.5 kg but most of the responders had shorter duration of diabetes and had received structured individualised weight maintenance advice [12].

Around 25% (n=36) of the participants lost at least 15 kg of weight. At 24 months, 35.6% (53/149) of those in the intervention group remained in remission compared to 3.4% (5/149) in the control group. The adjusted mean difference in body weight change in between the control and intervention groups was −5.4 kg (95% CI −6.9 to −4.0; p<0.0001) and in HbA1c was −4.8 mmol/mol. Of those maintaining ≥10kg weight loss, 64% (29/45) achieved remission. Serious adverse events were similar at 12 months, but were fewer in intervention than control group in the second year [23].

The short-term effects (i.e. <6 months) of VLCD in overweight patients with T2DM were found favourable on hypertension, dyslipidaemia, and HDL Cholesterol [24-26]. However, it is not clear whether this is due to the associated weight loss [27].

Weight regain while readjusting to normal eating after the VLCD can be a problem. This can be influenced by definitive prescription of food type and amount during the food reintroduction and weight maintenance phase [12].

Although bariatric surgery is recommended as a management tool for obese patients with T2DM, the prospect of bariatric surgery being offered to every eligible individual is minimal because of limited resources [21]. In an observational study, patients with T2 DM who met the eligibility criteria for bariatric surgery were recruited in a 12 weeks programme of very low-calorie diet and had counselling in low to moderate intensity physical activity. The results showed short time weight loss, reduced need for pharmacologic therapy and dramatic improvement in HbA1c particularly in patients with newly diagnosed diabetes [28].

In another study, two groups of subjects aged 18-65 years with BMI >35 kg/m2 followed by HbA1c 6.5-12% (48-108 mmol/mol) were recruited to analyse the effectiveness between Roux-en-Y gastric bypass and VLCD. The assessment between two groups consisting of individuals who were scheduled to undergo RYGB (n=11) or willing to participate in a nonsurgical inpatient VLCD programme (n=14) concluded that Roux-en-Y gastric bypass was not superior to VLCD with regard to early changes in beta cell function in obese subjects with T2DM [29].

In early 70’s, there was concern about the modified fasting diets. It was widely believed that rapid weight loss leads to a greater weight gain although an RCT among 204 participants showed that there was no difference of weight regain following a 12-week rapid weight loss programme or a 36 weeks gradual programme at 144 weeks follow-up [30].

Guidelines published in some western countries (e.g. USA) advocate the use of very low calorie/energy diets for weight management, under careful supervision of trained healthcare professionals [31, 32].

The acceptability of VLCD among patients is generally good. Various factors play a role including the potential weight loss, possibility of diabetes remission, and long-term health improvement [33]. In order to maintain weight after successful weight loss, a behavioural change is required. Behavioural therapy and cognitive behaviour therapy (CBT) are potential psychological interventions facilitating better maintenance of weight loss particularly when combined with diet and/or physical activity [34]. A longer duration of the intervention and more frequent clinical contact was associated with an increased effect. However, studies with substantial follow-up (i.e. >2 years) are lacking [2].

Tolerability, cautions and side effects with VLCD

VLCD is generally well tolerated in majority of patients although due to rapid weight loss and mild ketosis, some patients can experience headache, constipation, hair loss, irritability, lethargy, menstrual irregularities and postural hypotension [35]. Patients can generally handle ketone/acid loads well unless they have advanced kidney disease. There is not much data available with VLCD in patients with background end stage chronic kidney
Role of Very Low Calorie Diet in Type 2 Diabetes Mellitus: A Mini Review
