Abstract

Objective: to describe the physical characteristics and biological of the wires of more sutures used in surgical practice daily and their indications.

Methods: Review was conducted of literature through to search in the databases PubMed, Embase, Web of Science and Scopus. Results: were described data on the qualities of the ideal suture, general classification and descriptive, criteria for use and the physical and biological characteristics of absorbable sutures, wires, monofilaments and multifilamentary. Conclusion: it was possible to synthesize the current knowledge the respect of strands of suture, to be used by students of medicine, surgery residents, surgeons and its subspecialties.

Keywords: Sutures; Sutures Materials; Polymers; Absorbable Effect; Non-Absorbable Effect Suture; Biocompatible Materials;

Introduction

The suture thread began to be used for closing wounds 3,500 years before Christ in Egypt \cite{1} and to this day the act of stitch is still the most common method for rapprochement of the edges of the surgical wounds. The suture material selection should be based on the biological properties of the tissues to be approximated, in the physical and biological characteristics of yarns and wound conditions to be closed. Even with the current advance of technology; it remains true that no suture has all the features that classify as the ideal wire.

Qualities of the ideal suture

- Appropriate resistance.
- Minimal tissue reaction.
- Do not degrade into toxic products.
- Not facilitate the infection and remain stable in your presence.
- Arms and constant resistance.
- Coefficient of friction fit.
- Ability to maintain the resistance until when needed.
- Absorption speed unaffected by body fluids.
- Be easy to handle - easy knot and firm.
- Appropriate elasticity
- Not be changed with the sterilization.
- Have low penetration.
- Non allergenic and non-mutagenic.
- Be low cost.

Objective

Describe the physical and biological characteristics of the sutures used in surgical practice daily and their indications.
Methods

Literature review was performed by searching in the databases PubMed, Embase, Web of Science and Scopus on the topic, using the following keywords: sutures, sutures materials, polymers, suture, absorbable effect, non-absorbable effect suture, biocompatible materials. Were described data on the qualities of the ideal suture, general classification and descriptive, criteria for use and the physical and biological characteristics of absorbable sutures, wires, monofilaments and multifilamentary.

Results and Discussion

The suture can be classified according to several parameters that relate to your source material, structure and permanence in the tissues. So, as the degradation that they suffer in vivo is classified into two broad categories as absorbable and non-absorbable sutures, both with wires that are manufactured from natural fibers or synthetic materials. Although the natural fiber yarns have been used for a long time and to this day are with good results, the most modern synthetic yarns are considered more suitable. Among other reasons, by the lower tissue reaction when compared to natural or organic yarn [2]. The sutures may also be characterized by your physical setup. Those consisting of a single filament are said monofilaments and the formed by multiple fibers, braided or twisted, are called multifilamentary. The nylon and the steel are examples of yarns available both as monofilaments and multifilamentary.

The general classification of the suture can be seen below, where trade names have been added to some of them, with the sole purpose of facilitating the identification of the same.

The decision of using absorbable, monofilament or multifilament, not absorbable depends of a series of factors. There is that if you consider the time needed for the wound to heal, the voltage supported by tissue during the healing process and the issue of temporary or permanent need of the suture to ensure mechanical support. Experimental studies have revealed that the wires of suture in wounds of abdominal wall stopped to engage mechanical support between the days 15 and 28 of the postoperative period [3], and that only 41% of aponeurosis regained your initial resistance 2 months after being sutured [4]. Both findings like these, as the complex dynamics of muscle structures and aponeurotic of the abdominal wall and your susceptibility to incisions hernias and event, have provoked discussion about the choice of the best suture thread being used.

The variations in the behavior of the different types of suture materials have been widely studied in vivo, in vitro, experimentally and clinically, each study emphasizing the qualities of each one of them. In general, the monofilaments are appointed as more advantageous, because the multifilamentary provide conditions for the development of infection, since bacterial colonies are formed in spaces between filaments [5, 6]. Absorbable natural yarns (catgut) are responsible for the most intense inflammatory reaction among all suture, besides presenting a time very short and unpredictable absorption. The emergence of the synthetic absorbable was very promising for several reasons: a) trigger inflammatory reactions significantly smaller than natural absorbable; b) keep much of your resistance until the absorption process begins and if complete; c) are available with times of absorption short, medium and long, giving opportunity to the surgeon choose the suitable wire for each case; d) quality mechanics of us is the same for all the wires tested synthetic absorbable [4-6].

The description of each suture is made below.

Absorbable

Catgut

Yarn made from collagen extracted from the sub mucosa of the small intestine of sheep or cattle intestinal serosa, is available in the form of catgut simple and catgut chrome. The simple loses half of strength after 5 to 7 days in the tissues and 100% after 3 to 4 weeks. The treatment with chrome wire extends absorption and increases your resistance to stress. The catgut chrome loses 50% of the resistance in the 20 days 19 and 100% after 5 weeks in the tissues. It is a monofilament wire, absorbed by the mechanism of enzymatic digestion, which causes tissue significantly more intense reaction than the synthetic absorbable [7].

Should be avoided in suturing of tendons and fasciae, since they are healing slowly, structures that are subjected to efforts and constant tensions. In addition, the time of absorption of catgut is unpredictable. Is contraindicated in bleeding duodenal ulcers sutures or perforated, pancreaticojejunal anastomosis and biliary anastomosis, because it can be quickly disintegrated by the action of proteolytic enzymes [8].

Polyglycolic Acid (Dexon)

Multifilament yarn, braided synthetic absorbable by hydrolysis, in which is released the monomer glycolic acid soluble. It has been shown experimentally that the polyglycolic acid loses your strength after 28 days altogether in the tissues and is 100% absorbed within 60 days. As for postoperative adhesions, in the form of gel can reduce the formation of pericardial adhesions [9, 10]. Clinical study showed that the closure of abdominal wall with Polyglycolic Acid resulted in 16% of infection, significantly higher than the 7% of infection that occurred when the wounds were closed with absorbable monofilament synthetic [11].

Polyglactin 910 (Vicryl)

Multifilament consists of 90% to 10% glycolic acid and lactic acid. About 50% of the yarn is absorbed by hydrolysis after the 28th day after surgery and 100% after the 70th day [12]. When compared with the polidioxanona (PDS) in intradermal suture on the presence of erythema, in duration, hypertrophic scarring and infection, there was no significant difference [13]. Used in experimental rabbits, pyloroplasty, proved to be the most suitable wire compared to other natural and synthetic resorbable wires [14].

Suture materials interact with immunocompetent cells and may affect host immunity. In experimental work was studied the influence of soluble factors of multiple sutures on the function of...
macrophages. It was found that your capacity for phagocytosis, adherence, lysozyme and production of tumor necrosis factor was significantly more affected by polyglactin, in comparison with the other wires [15].

**Polydioxanone (PDS)**

Monofilament yarn produced from the polymerization of polydioxanone. Of violet color, absorbed by hydrolysis, your time of absorption is more extended than polyglactin. Study in rats showed that the polidioxanone was present in vascular anastomoses after 120 days, suggesting that this material is safe in vascular sutures [16].

On average, the absorption of the wire starts after 90 days and ends after 180 days. Anastomosis and micro anastomosis performed showed that the polidioxanone provoked little inflammatory reaction when compared with other materials of suture [17,18]. Study *in vitro* showed that the wires of suture release factors influencing behavior considerably immunotoxic macrophages and that these effects may have important clinical implications. One of the wires tested in the study, the polidioxanone and steel was the materials that have less inhibition of macrophage functions [15].

**Poliglecaprone (Monocril)**

Absorbable, monofilament is a copolymer of epsilon-caprolactone and glycoside. Laboratory tests have shown that shows excellent ease of handling, minimal resistance during passage through the tissues and resisting proper tension. The time of complete absorption between 90 and 120 days of deployment in the tissues, with minimal tissue reaction [19].

**Polyglyconate (Maxon)**

Slow absorption monofilament, features high resistance. Randomized clinical study showed that polyglyconate, even used with smaller diameter than the polyglycolic acid, retained high strength tension postoperatively, when employed in the closure of abdominal wall [20]. When it comes to sutured, presented infection rate significantly lower (7%) on laparotomies lock, of abdominal wall [20]. When it comes to sutured, presented strength tension postoperatively, when employed in the closure with smaller diameter than the polyglycolic acid, retained high resistance [23]. This loss is resistance by chemical degradation and not by physical phenomena as exhaustion of matter or undone the knots. Proteolytic enzymes cause hydrolysis to attacking the amide group of the polymer, resulting in 1-6-hexanediamine and adipic acid.

Rats showed that the polidioxanone was present in vascular anastomoses after 120 days, suggesting that this material is safe in vascular sutures [16].

**Non absorbable Sutures**

**Cotton, linen and silk**

Are multifilamentares of natural fibers, yarns have high resistance, are easy to handle and provide firm mechanical node. His great virtue is the low cost, reason by which still today are widely used in many hospitals. For being multifilamentary of high capillarity, leverage infection more than monofilamentares wires nonabsorbable sutures. The intense inflammatory reaction causing decreases tissue resistance to infection and multifilament structure retains the bacteria in your intimacy. This facilitates wall infection, fistula formation and the elimination of through points of operative wounds. This way, these wires should be avoided in wound suture that present bacterial contamination. Silk, in particular, exerts a considerable inhibitory effect on the functions of macrophages, harming mostly the adhesion of these cells [15].

**Polyester (Dacron, Mersilene)**

Manufactured through polymerization resulting ester ethylene glycol combination with terephthalic acid, multifilament, braided, is of high resistance. By beawire of high coefficient of friction, the handling is not of more easy, that makes your limited use. The us present unfavorable mechanical qualities, which made trying to improve quality coating your surface with teflon, silicone and polybutylate, targeting also decrease your capillarity.

Polyester induces a significantly higher tissue reaction of the polypropylene in abdominal wound closure, with increased risk of infection [22]. The addition of inert materials and waterproof cover polyester filaments did not alter significantly the tissue inflammatory response, did not decrease the incidence of infection in contaminated wounds sewn up with this thread. Therefore, should be avoided in wounds with these characteristics.

**Polyamide (Nylon)**

Available as monofilament and multifilament, braided nylon causes little tissue reaction, can be used and is well tolerated in infected tissues in presentation monofilament. Is a low-cost, easy to handle, but we can dispose very easily. This requires the surgeon to make multiple nodes at each point of a suture, doing with that bacteria proliferate in the recesses of these nodes.

Had once as chemically inert material, nylon decomposes over time in 1-6-hexanediemide and adipic acid, so that after 6 months in the tissue loses almost entirely your resistance to tension [23]. This loss is resistance by chemical degradation and not by physical phenomena as exhaustion of matter or undone the knots. Proteolytic enzymes cause hydrolysis to attacking the amide group of the polymer, resulting in 1-6-hexanediemide and adipic acid. *In vitro* study indicated a probable antibacterial action of these degradation products of nylon, able to reduce the number of colonies of *Staphylococcus aureus* at concentrations varied [3]. However, when the wire was deployed in the subcutaneous tissue of rats for a prolonged period, their supposed degradation products did not show any antibacterial action [24].

**Polypropylene (Prolene, Surgilene)**

Monofilament wire, available in blue color, biologically inert even in the presence of infection. Is easy to handle, the node is firm, has proper elasticity and wide chemical resistance to acids, alkalis and enzymes. Its resistance to tension remained unchanged in tests conducted after several years of deployment in the tissues. Polypropylene has great tensile strength, although
it can easily be fractured by the needles, as often occurs with the monofilamentares. High resistance, combined with the appropriate elasticity, makes him a suitable wire for vascular anastomosis, anastomosis of tendons and suture of abdominal wall [25, 26].

**Polytetrafluoroethylene (PTFE)**

- Is a non-absorbable monofilament wire, tested with good results in plastic surgery. In a comparative study with 10 other sutures, it was verified that the PTFE caused the less tissue reaction, making him considered the wire of choice for facial plastic surgery, where the critical functional and aesthetic results [27].

**Polybutester (Novafil)**

- Monofilament non-absorbable synthetic which offers elasticity, flexibility and resistance to thevoltage that the sensitive of the other of the same category. The degree of elongation at break time and safety of us are similar to those found in other sutures Nonabsorbable sutures, synthetic monofilamentares [28]. These features make it potentially beneficial for closure of the abdominal wall [29]. The wire has been tested on the skin of the abdominal wall to gauge the degree of hypertrophy and scar width, and the presence of transverse markings. The authors concluded that the polybutester decreases the risk of hypertrophic scar by own particular elasticity, which allows adaptation of the tissues the tension is exerted on them. When compared with the nylon, proved to be superior in all parameters studied [28]. In vascular anastomoses, the polybutester showed great ease of handling, knot tight and most appropriate elasticity that polypropylene to monitor compliance of vessels [30].

**Steel (Aciflex)**

- The relatively high infection rate found with the use of steel mono or multifilamentary can be the result of their physical and chemical characteristics. The steel is not as inert as the synthetic polymers. The metal can degrade through corrosion or chemical characteristics. The steel is not as inert as the polybutester, showing minimum elongation of the multifilament and stainless steel better retention capacity of the node, resulting in a higher ultimate tensile strength in repairs of tendons [27,33].

**Conclusion**

- In conclusion, the existing knowledge of sutures and their biophysical chemistry characteristics contributes to the surgeons decide the proper use of these during surgical synthesis, contributing to best postoperative results, avoiding rejections, infections and other complications inherent to the operative procedure, favoring a speedy recovery of the patient with therapeutic costs reduction.
